Abstract

There are many way to protect code from reverse engineering. One such way is to obfuscate either the source code, machine code or bytecode. Obfuscating Android applications not only makes it harder to reverse engineer, it can also speed up execution by reducing the size of the application and removing unnecessary code. One method of obfuscation is to do it manually and the other method is to use an obfuscation program. However, it may become necessary to reverse obfuscation, because of the loss of source code or when investigating malware, trojans, or other harmful applications. This process is called deobfuscation. Once an application has been obfuscated performing deobfuscation is a tedious task, and knowing how the application was obfuscated would increase the probability of correctly reversing the obfuscation. By examining four Android application obfuscators I successfully identified distinct fingerprints within each of the obfuscated binaries by building a simple Android application, obfuscating it, and then comparing obfuscated and unobfuscated bytecode. Using these fingerprints I was able to associate each obfuscator with an approximate probability that it was used to perform the obfuscation.

Acknowledgments

I thank Dr. Brian Hay, Department of Computer Science, University of Alaska Fairbanks, Dr. Orion Lawlor, Department of Computer Science, University of Alaska Fairbanks, Dr. Kara Nance, Department of Computer Science, University of Alaska Fairbanks, and Dr. Jon Genetti, Chair of the Department of Computer Science, University of Alaska Fairbanks, for their guidance, technical knowledge and support. I would also like to thank my fellow graduate student Karl Ott, for his technical knowledge and support. I would also like to thank my parents Robert Van Veldhuizen and Patricia Holloway for proof reading my paper.

1 Introduction

The Android smart phone is one of the best selling smart phone platforms in the world [31], with more than 1.5 billion Android smart phones sold between 2010 and 2013 [40]. In addition, the Android smart phone has the largest install base of any mobile or non-mobile operating system, and since 2013 there have been more Android devices sold than Windows, iOS and Mac OS X devices combined [40]. With this many Android devices in use today, security is very important.

There are a multitude of options when it comes to security in Android devices, and most methods include a combination of physical, web, or intellectual processes [10, 31]. However, security begins with the developer. For example, a developer has created an application for the Android platform with an algorithm that will out perform all competitors. The new algorithm may be protected from being reverse engineered by using a method called obfuscation [33]. Obfuscation is a process of making the source code, machine code, or bytecode, difficult for humans to understand, while still being able to run normally. Obfuscated binary code prevents analysis from developing timely, actionable insights by increasing code complexity and reducing the effectiveness of existing tools [5]. While obfuscation is great for hiding the developer's new algorithm, it can also be used by individuals who wish to harm users. For instance, developers of malware, trojans, or viruses, can use obfuscation to make it difficult for computer security professionals to discover what a potentially harmful application is doing [28, 29].

Regardless of the intent of the developer, there are two methods that can perform obfuscation [30]. One method is to use a tool or application that will obfuscate the Android application automatically. The developer only needs to set up the obfuscation settings and run the obfuscator on the original application. The other method is to manually obfuscate the application. While this method is more time consuming and difficult, it does produce a unique application in the end. The process of reversing obfuscation is called deobfuscation. Deobfuscation means taking obfuscated source code, bytecode, or machine code that is difficult to understand, and transforming it back into code that can be understood by humans [30]. Performing deobfuscation is a tedious task, and knowing how the application was obfuscated would increase the probability of correctly reversing the obfuscation [33].

The intent of this project is to address the following research questions related to the obfuscation of Android applications:

- Within each obfuscation, whether it was done manually, or with an obfuscation program, are there any differences between them that could be used as reliable markers to correctly identify how it was obfuscated?
- If such markers are found, would it be possible to generate a distinct fingerprint for each of the obfuscation programs that would correctly identify it?

The objectives of this project were to examine a small subset of the automatic obfuscation programs, each with different methods for performing obfuscation and identify how an application was obfuscated. My goal was to determine if it is possible to identify which obfuscation program was used on any Android application, based on a distinct fingerprint for each obfuscation program.

2 Related Work

Dr. Yiannis Pavlosoglou, researched this same topic but for Java applications. He developed a program called elucidate [25], which is a Java Obfuscator Fingerprinter and Cracking tool. This tool was able to identify the obfuscator, recover known strings within the file, give an estimate of the complexity, and provide a map of the application given a jar or class file. Dr. Pavlosoglou provided me with a set of lecture slides and sources but was unable to recover the original elucidate tool. This tool was only able to look at Java bytecode and not Dalvik bytecode. Most of Dr. Pavlosoglou's research was targeted for Java. While Java and Dalvik are similar, the Dalvik Virtual Machine has completely different set of bytecode instructions. Consequently, obfuscation tools Dr. Pavlosoglou mentioned in his presentation are either not relevant to Android or no longer available.

3 Background Information

3.1 Terminology

3.1.1 Android Application Package (APK)

Android Application Package is the package file format used to distribute and install application software and middleware onto the Android Operating System. It is based on the ZIP file archive structure [38].

3.1.2 Dalvik Virtual Machine

Dalvik Virtual Machine is a process virtual machine on the Android Operating System that executes applications written for Android. Programs are commonly written in Java and compiled into Java bytecode and then translated into Dalvik bytecode [38]. There are several reasons the Dalvik Virtual Machine is used over the Java Virtual Machine for smart phones. One such reason is that the Virtual Machine was slimmed down to use less space. In addition, the Dalvik bytecode instruction set is more suited for register based machines, which lowers the number of total instructions and raises the instruction interpreter speed. Another reason the Dalvik Virtual Machine is used for smart phones is that it has been optimized heavily to work with low memory [34].

3.1.3 Deobfuscation

Deobfuscation is the process of converting a program that is difficult to understand (in other words, a program that has been obfuscated) into one that is simple to understand [20].

3.1.4 dex

Dalvik Executable, otherwise known as dex, is the bytecode to be executed on the Dalvik Virtual Machine [7].

3.1.5 bytecode

Bytecode is a form of instruction set designed for efficient execution by a software interpreter. As long as there is an interpreter, the bytecode can be run on any hardware and operating system configuration.

3.1.6 Fingerprints

Fingerprints are distinct identifiers within the application that can be used to identify various characteristics about the application such as how it was obfuscated, how the application was written or what machine compiled the application [39].

3.1.7 Obfuscation

Obfuscation is the deliberate act of creating obfuscated code, such that the source or machine code is difficult for humans to understand but will still work properly when executed or compiled [20].

3.1.8 Obfuscator

An obfuscation application that will generate an obfuscated version of the target application.

3.1.9 Software Development Kit (SDK)

A Software Development Kit is typically a set of software development tools that allow for the creation of applications for a certain software package, framework, hardware, or operating system [41].

3.2 Android Platform

The Android Platform is an open source operating system designed for mobile, embedded and wearable devices. The operating system is based on the Linux kernel and is currently being developed by Google. The operating system uses the Dalvik Virtual Machine with a Just-In-Time compiler to execute Android applications. Android applications are written in Java and then compiled into the Dalvik bytecode, or dexcode, Figure 1 shows the differences between the steps in which Java and Dalvik bytecode are compiled [6].

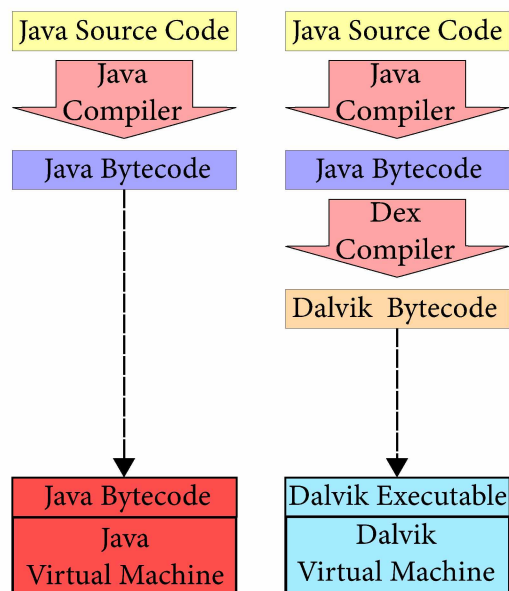

Figure 1: Different Steps Between Compiling Dalvik and Java bytecode.

During the build process the Android applications are encapsulated in an APK archive. The APK is a compressed file, very similar to a compressed Zip archive [31] that contains the class bytecode and all the application resources (icons, sounds, etc), and any binary native files. For each Android application a manifest file is required. The manifest file defines the metadata for the application. The metadata includes the requested permissions or registered services and activities. Activities are screens that allow the user to interact with the program.

3.3 Android Obfuscation

3.3.1 Identifier renaming

Identifier renaming is one of the simplest methods of obfuscation. It operates by changing the names of variables, functions, or methods from their original identifier names to a name that is less meaningful or harder to understand. Figures 2 and 3 show an examples of identifier renaming [21].

```
public class Base64 {  
    public String decode( String input )  
    { ... }  
    public String encode( String input )  
    { ... }  
}
```

Figure 2: Java Source Code

```
public class a {  
    public String a( String a )  
    { ... }  
    public String b ( String b )  
    { ... }  
}
```

Figure 3: Java Source Code with Rewritten Identifiers

3.3.2 Junk Byte Insertion

Inserting junk bytes into the software complicates the analysis of the binary. There are two assumptions that have to be considered. First, the instructions have to be incorrect by using incomplete instructions. This produces a “red herring” for disassemblers. The second assumption is that the incomplete junk byte instructions must never be reached during normal execution. This is achieved by placing an unconditional jump before the inserted junk byte instructions or a conditional jump if the result is known and predictable. Figure 4 shows that the integer 6 is returned, and due to the unconditional branch at address 0x3be (shown in red), the inserted junk bytes (shown in blue) will never be executed.

Figure 5 is the same code as Figure 4, but was analyzed using a linear sweep algorithm. This algorithm fails to disassemble the junk byte code. Linear Sweep starts at the first byte of the binary’s text segment and proceeds from there, decoding one instruction at a time. They are prone to errors that result from data embedded in the instruction stream. Thus resulting in errors when trying to decode the junk bytes that were inserted [19].

0003bc: 1250	0000: const / 4 v0, #int 5
0003be: 2900 0400	0001: goto / 16 0005

0003c6: d800 0000	0005: add-int / lit8 v0, v0, #int 1
0003ca: 0f00	0007: return v0

Figure 4: Disassembly with Detection of Junk Bytes

0003bc: 1250	0000: const / 4 v0, #int 5
0003be: 2900 0400	0001: goto / 16 0005
0003c2: 0001 0000 d800 0001	0003: dummy-function
0003ca: 0f00	0007: return v0

Figure 5: Linear Sweep with dexdump Fails Due to Junk Bytes.

Figure 6 is the same as Figure 4, but was analyzed using a recursive traversal algorithm, and the conditional branch led to a failure of the disassembler. Recursive traversal works by following the control flow of the program, which makes it possible for the disassembler to skip any junk byte data that had the conditional branch before it. However the control flow cannot always be reconstructed precisely because it can be influenced by external processes such as the run time state or other conditional branches. These external processes are not available to the disassembler during static analysis, and only during run time. When the algorithm cannot determine the jump location statically, for instance in the case of an indirect jump, it fails to analyze parts of the programs code [19].

0003bc: 1250	0000: const / 4 v0, #int 5
0003be: 2900 0400	0001: if-gtz v0, 0005
0003c2: 0001 0000 d800 0001	0003: dummy-function
0003ca: 0f00	0007: return v0

Figure 6: Recursive Traversal Fails Due to Conditional Branches.

3.3.3 Obfuscated or Encrypted Strings

The use of encryption renders strings unreadable. The strings are stored as clear text inside the compiled Android application, which makes extraction trivial. To obfuscate strings, the strings are encrypted and stored inside the application. When the strings are needed during run time, they are decoded or decrypted. Once they are decoded they can be used normally inside the application. Figure 7 shows the Java method with unencrypted strings and Figure 8 shows the same method but with encrypted strings [21].

```
public void init() {
    String host = "www.example.com";
    String username = "secretuser";
    String password = "secretpass";
}
```

Figure 7: Java Source with Unencrypted Strings.

```

public void init() {
    String host = decrypt("b4177923565cfbe84eae33e4efdb637a");
    String user = decrypt("a58be63b1602ab2a6ac24d9a4689d278");
    String pass = decrypt("a0133dc939c4f54571faf329a904a3ec");
}

```

Figure 8: Java Source with Encrypted Strings.

3.3.4 Dynamic Loading of Code

When a program is running and during execution, code from a remote location is loaded and executed. The Android specific method of fetching, embedding and if necessary, unpacking or decrypting the remote code parts is simply by using readily available library functions such as the `java.net.url` and `javax.crypto.cipher` libraries. Both loading and execution are possible through the standard `DexFile` class. It is possible to load a dex file into memory of the currently running process [21].

3.3.5 Dynamic Code Modification

Dynamic code modification increases the difficulty of static analysis especially when employing multiple layers of modification. There are two different ways to accomplish dynamic code modification [21].

The first method is to modify the Dalvik byte code itself. The Dalvik byte code has a limited instruction set, meaning that it is not possible to alter the bytecode dynamically without the use of an external helper. Using the Java Native Interface [26], it is possible to execute native code in the context of the currently running process, and therefore the native code can access memory. This native code has to be called and loaded by the Dalvik bytecode, and it produces bytecode that will further be executed by the Dalvik Virtual Machine.

The second method is to execute native code directly by the processor. There are several differences between the instruction sets of Intel x86 and ARM, but dynamic code manipulation is very similar to the well known and much discussed techniques on x86 machines [31]. This technique is not considered for the purposes of this project.

3.3.6 Call Graph Obfuscation

Every Android application begins as a fork of the Android zygote process. This zygote process has a set of libraries and the Android framework preloaded. This obfuscation method works by including classes into the APK that have the same name as one of the preloaded system libraries. The resulting Dalvik bytecode will point to the internal library definition, but during run time it will use the preloaded library [21]. Figure 9 shows how Call Graph Obfuscation works.

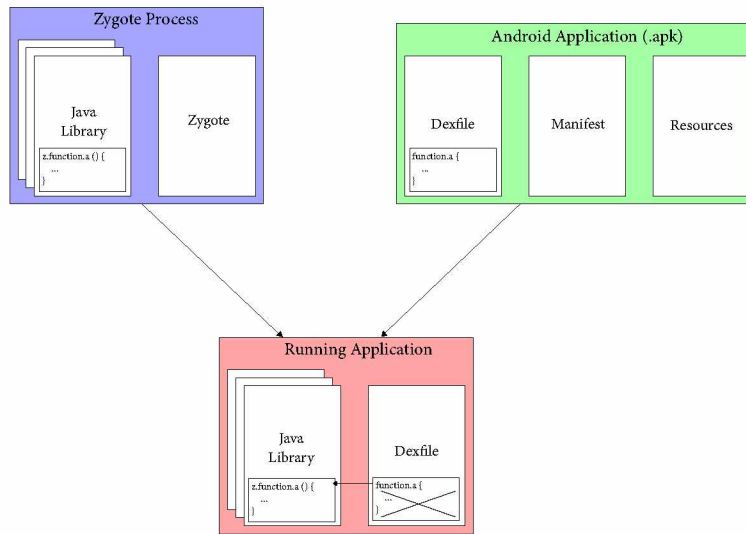

Figure 9: Call Graph Obfuscation.

3.3.7 Manifest Obfuscation

Every android application has a manifest file that defines the application's metadata. This metadata stores information about the requested permissions, registered services, and activities. Activities are an application component that provides a screen that the user interacts with, such as dialing the phone, taking a photo, sending an email or viewing a map. Each activity is given a window that can either fill the screen or be a smaller, floating window on top of other windows. Android itself looks for certain attributes by a numeric identifier instead of a name. However, static analysis tools drop the attribute ID and instead leave the attribute name intact. This can be exploited by including an attribute with an invalid ID (0x00000000) in the application's manifest file [21]. Android will ignore the attribute since it is invalid, but static analysis tools will drop the ID when decoding the Android manifest file, and only consider the attribute name. This means that any entry in the manifest will be ignored by Android at run time, but any static analysis tools will attempt to decode the ID and will fail and report back as either a bad manifest file or corrupted application package.

```

<manifest xmlns:android="http://schemas.android.com/apk/res/android"
    android:sharedUserId="string"
    android:sharedUserLabel="string resource"
    android:versionCode="integer"
    0x00000000="string"
    . . .
</manifest>
  
```

Figure 10: Manifest Obfuscation Example.

4 Tools

4.1 Android Obfuscators

4.1.1 Proguard

Proguard [8] is an Open Source Java and Android obfuscation tool that can shrink, optimize, obfuscate and preverify Java classes. It comes with the Android SDK and comes preconfigured for most purposes. It can:

- Detect and remove unused classes, fields, methods and attributes.
- Optimize bytecode and remove unused instructions.
- Rename classes, fields and methods using short meaningless names.
- Preverify the processed code for Java 6 and higher.

4.1.2 Java Archive Grinder

Java Archive Grinder [23] is an Open Source Java optimizer, obfuscator, shrinker, and reducer. It can:

- Remove unused fields, methods, classes and interfaces as well as debug information.
- Rename fields, methods, classes and interfaces.
- Optimize Java bytecode, such as removing NOP instructions and compressing local variable slots.

4.1.3 Zelix KlassMaster

Zelix KlassMaster [42] is a commercial Java and Android bytecode obfuscator. It can:

- Rename methods, fields, and classes.
- Implement flow control, exception, and string obfuscation.
- Integrate with Apache Ant build system to work with Dalvik bytecode obfuscation.

4.1.4 Allatori

Allatori [1] is a commercial Java and Android Obfuscator where it can:

- Do name and flow control obfuscation.
- Obfuscate debug information as well as string encryption.
- Work with the Apache Ant build system to work with Dalvik bytecode obfuscation.

4.2 Android Obfuscators Considered But Not Used

The following obfuscation applications were considered when doing this project, but in the course of examination they were discounted due to one or more factors that made their use impractical for this project. These obfuscators were considered due to their past popularity with Java obfuscation, and their stated ability to work properly when obfuscating Android applications.

4.2.1 ClassEncrypt

ClassEncrypt [37] is an Open Source Java obfuscator that can encrypt class files to prevent malicious users from stealing the source code. This obfuscator was not used because every time it was executed, it produced empty Java class files, and gave no errors, even with different settings applied.

4.2.2 Java ByteCode Obfuscator

The Java ByteCode Obfuscator [3] is Open Source Java bytecode obfuscator based on Soot's advanced typing and flow analysis framework to perform obfuscation. It can:

- Operate on Java class files, producing obfuscated Baf, Jasmin, or class files.
- Add dead-code switch statements, disobey constructor conventions, flow control obfuscation, and package local variables into bitfields.
- Rename class, method, field, or variable names.

This obfuscator was not used because it was not compatible with the Android bytecode, even when it was converted to Java bytecode before running the obfuscator. It required that a Main function be defined in order to properly obfuscate and Android does not use Main to start the application.

4.2.3 Java Optimize and Decompile Environment

The Java Optimize and Decompile Environment [15] is an Open Source Java decompiler and optimizer. It can:

- Rename class, method, field, and local names to shorter, obfuscated or unique names or according to a given translation table.
- Remove debugging information, dead code, and constant fields.
- Optimize local variable allocation.

This obfuscator was not used because every time it was run, it produced different exception errors, even when the same input was given and the same settings were applied.

4.3 Tools Used

4.3.1 Apache Ant

Apache Ant [12] is a software tool for automating the software build process for Java and Android. It uses a set of XML files to describe the build process and its dependencies. Apache Ant was designed to be modular so that changing or adding in new steps in the build process is simple and efficient, usually called Ant Tasks. Several of the obfuscators mentioned, included Ant Tasks to be implemented when building the Android Application with their obfuscator.

4.3.2 dex2jar

The dex2jar tool [27] is a Unix and Windows command line tool that can translate Dalvik bytecode to Java bytecode.

4.3.3 dexdump

The dexdump tool is a Unix command line tool that was bundled along with the Android SDK. The dexdump tool is a static disassembler for Dalvik bytecode. It provides information about the Android application by looking at the classes.dex file inside the APK.

4.3.4 jar2dex

The jar2dex tool [27] is a Unix and Windows command line tool that can translate Java bytecode to Dalvik bytecode.

4.3.5 unzip

The unzip tool [14] is a Unix command line tool that will list, test or extract files from ZIP archives.

4.3.6 xxd

The xxd tool [36] is a Unix command line tool that creates a hex dump of a given file or standard input. It can also convert a hex dump back to its original binary form.

5 Building Android Applications with Obfuscation

The first step in finding obfuscation fingerprints was to look at the differences between an unobfuscated Android application and an obfuscated Android application. To make this comparison easier to achieve, a simple Android application was written. Each time the Android application was compiled and built, a different obfuscator was used. After all of the applications were obfuscated, each application was disassembled and compared against the unobfuscated disassembly.

5.1 Simple Android Application

The Android application that was written included four parts: the main activity, string encryption activity, Fibonacci calculator activity, and get web page activity. Each of the activities attempted to achieve some functionality that could be found in many Android applications. This would result in seeing obfuscation that could be used to identify their correlating fingerprints. Each activity also included extraneous and unused variables and classes that would be affected by each of the obfuscators. The source code for this application is located in Appendix A.

5.1.1 Main Activity

The main activity included three input entry boxes with accompanying send buttons. Input was entered, the *Send* button was pushed, and the corresponding activity was called and executed. The main activity can be seen in Figure 11. The Java code for this activity is located in Appendix A.3 while the activity XML is located in Appendix A.4.

5.1.2 String Encryption Activity

The string encryption activity used the text entered into the main activity and encrypted it. It would then display the encrypted text in a new activity window. The string activity can be seen in Figure 12. The Java code for the string encryption is located in Appendix A.5 and the encryption code is located in Appendix A.6 and the activity XML is located in Appendix A.7.

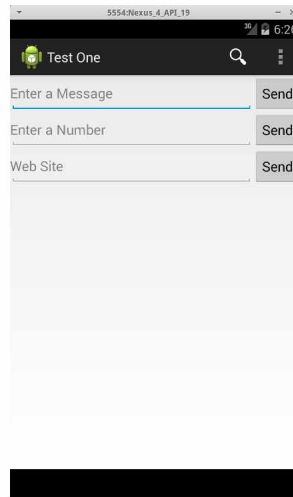

Figure 11: Main Activity Screenshot.

Figure 12: String Encryption Activity Screenshot.

5.1.3 Fibonacci Calculator Activity

The Fibonacci calculator activity takes input from the main activity as an integer and calculated the Fibonacci number up to the given number. Two versions of the Fibonacci Calculator were written. One that correctly handled very large numbers, and one that did not, which causes integer overflow, see Figure 13. The Java code is located in Appendix A.8 and the activity XML is located in Appendix A.9.

Figure 13: Fibonacci Calculator with and without Overflow Activity Screenshot.

5.1.4 Web Page Activity

The web page activity used input from the main activity in the form of a URL and displayed the associated web page. This activity was not fully implemented. It was able to make a connection to the specified URL, but it is not able to render the web page correctly. Having full functionality here is not important. The main point of this activity was to implement network activity and not to properly displaying web pages. This activity can be seen in Figure 14. The Java code is located in Appendix A.10 and the activity XML is located in Appendix A.11.

Figure 14: Web Page Activity Screenshot.

5.2 Apache Ant Build Process

Every application was built in release mode, digitally signed, and byte aligned. Release mode directs the build script to build the Android application so that it is ready for distribution to the end-users.

This mode removes some information from the resulting APK and requires that it be signed with a keystore. Therefore, a signed key was generated and included along with each application. After the application had been signed it was properly byte aligned, meaning the APK archive was aligned to ensure that all uncompressed data started with a particular alignment relative to the start of the file. This allowed for the best compression rates as well as efficient and proper use of the APK's.

5.3 Proguard Obfuscation

Since Proguard is the default obfuscator released with the Android SDK, enabling Proguard was a simple task. Most of the Proguard settings enabled by default were acceptable to use when obfuscating. However the following settings were enabled to ensure strict obfuscation settings. For a full list of the settings Proguard used, see Appendices B.1 and B.2.

overloadaggressively

The `overloadaggressively` setting allows for multiple fields and or methods to use the same name. Any variable in one class could be named the same as a variable in a different class.

flattenpackagehierachy

The `flattenpackagehierachy` setting will repackage all the generated or included packages into a single parent APK package.

5.4 Java Archive Grinder Obfuscation

The Java Archive Grinder did not function properly as an Ant Task, therefore the resulting obfuscation had to occur after the APK was generated. This task was accomplished by opening the APK archive and finding the Dalvik bytecode, the `classes.dex` file. The `classes.dex` file was then converted to Java bytecode using the tool `dex2jar`. Once the Dalvik bytecode is converted, Java Archive Grinder could then be used. The Java Archive Grinder was set to obfuscate as strictly as possible. Once the obfuscator completed its task, it was converted back into the Dalvik bytecode, using the tool `jar2dex`, and repackaged into the original APK, replacing the old `classes.dex` with the obfuscated version.

When attempting to get the Java Archive Grinder to obfuscate as strict as possible it would fail. Java Archive Grinder was failing when attempting bytecode obfuscation. Therefore, the obfuscator was run with the `-nobco` or no bytecode obfuscation setting. This failure was possibly due to a conversion issue, when it was converted from dexcode to Java bytecode. It may not have correctly converted some of the bytecode. Alternatively, it may have been a problem with the version of the Java bytecode. The Java Archive Grinder obfuscator may have been written using an older version of Java, and could not understand some of the newer bytecode instructions.

5.5 Zelix KlassMaster Obfuscation

The Zelix KlassMaster obfuscator was compatible with the Ant build system. The easiest method of using KlassMaster was to replace the call to the Proguard program, with a call to the KlassMaster program. This would force Ant to use KlassMaster instead of Proguard when obfuscation was enabled. KlassMaster functioned by reading in a script file that has the obfuscation settings defined for the Android application. This settings file was generated with a tool that was provided along with KlassMaster that took the Proguard settings and generated an appropriate script file that KlassMas-

ter could understand. After the script file was generated, additional settings were applied to make the obfuscation as strict as possible. The full script is located in Appendix B.3. The following settings were included into the script.

obfuscateFlow

The obfuscateFlow setting will make slight changes to the bytecode that will obscure the control flow without changing the code functionality at run time.

exceptionObfuscation

The exceptionObfuscation setting is similar to the obfuscateFlow setting. It changes the exception handling of the bytecode.

encryptStringLiterals

The encryptStringLiterals setting encrypts all strings found in the bytecode constant pools. It adds code to the bytecode that will decrypt the strings at run time.

mixedCaseClassNames

The mixedCaseClassNames setting allows for any class to be named with a random set of characters of any case, upper or lower.

agressiveMethodRenaming

The aggressiveMethodRenaming setting allows for multiple identifiers to be renamed with the same name.

5.6 Allatori Obfuscation

Allatori worked with Ant by using an Ant Task. The Ant Task replaced the obfuscation call that would have executed the Proguard obfuscation, but instead executed the Allatori obfuscation. Therefore when running Ant it executed Allatori when the obfuscation step was processed. Allatori runs with a script that defined the settings for obfuscation. The full script is located in Appendix B.4. The script was changed to make the obfuscation as strict as possible. The following settings were added to the base script.

string encryption

This setting found all string data and encoded it, and also added in code to allow for the decryption of strings at run time.

control flow obfuscation

This setting changed the standard Java constructions (loops, conditional, and branching instructions) where possible, and altered the commands such that decompilation is more difficult.

line number obfuscation

This setting changed any of the line numbers.

remove toString

This setting removed any call to the toString bytecode instruction.

6 Android Obfuscation Fingerprints

After generating an obfuscated application using each of the obfuscators, the resulting APK's were unpacked to access the Dalvik bytecode file, classes.dex. Once the the classes.dex files were extracted each was opened with dexdump. This provided a static disassembly of the obfuscated dexcode. Each of the resulting dexdump outputs was then compared against the unobfuscated version of the same Android application. All of these dexdump outputs are located in Appendix C. Any difference from the unobfuscated and obfuscated dexdump was considered to be a part of the obfuscator's fingerprint. The following fingerprints were found for each of the obfuscators.

6.1 Proguard Fingerprints

The first difference that was discovered between the obfuscated and unobfuscated files was the removal of the BuildConfig Class. Figure 15 shows that the first class to be found in the obfuscated version was DisplayMathsActivity. No reference to BuildConfig was found in the obfuscated version.

Unobfuscated	Obfuscated
Class #0 header: class_idx : 16 access_flags : 17 (0x0011) superclass_idx : 46 interfaces_off : 0 (0x000000) source_file_idx : 10 annotations_off : 0 (0x000000) class_data_off : 11630 (0x002d6e) static_fields_size : 1 instance_fields_size : 0 direct_methods_size : 1 virtual_methods_size : 0	Class #0 header: class_idx : 15 access_flags : 1 (0x0001) superclass_idx : 2 interfaces_off : 0 (0x000000) source_file_idx : -1 annotations_off : 0 (0x000000) class_data_off : 6515 (0x001973) static_fields_size : 1 instance_fields_size : 0 direct_methods_size : 3 virtual_methods_size : 2
Class #0 Class descriptor : 'Lcom/uaf/matt/testone/ BuildConfig;' Access flags : 0x0011 (PUBLIC FINAL) Superclass : 'Ljava/lang/Object;' Interfaces : - Static fields : -	Class #0 Class descriptor : 'Lcom/uaf/matt/testone/ DisplayMathsActivity;' Access flags : 0x0001 (PUBLIC) Superclass : 'Landroid/app/Activity;' Interfaces : - Static fields : -

Figure 15: Comparison Between dexdump Output Showing the Class #0.

Secondly, the source_file_idx value was set to an invalid ID, and all annotation information was removed. The source_file_idx normally holds the index into the string_ids list that would hold the name of the source file. An invalid ID is set to -1 [4]. If annotations have been removed from the file, the annotations_off value would be set to 0. Otherwise there is no file offset to the location of where the annotations for that class occur. In addition, I discovered that Proguard renamed each of the variables. Proguard renamed each of the variables to a lower case letter in the alphabet. At the start of each class, Proguard restarted the variable names to the beginning of the alphabet. Figure 16 shows a comparison between the obfuscated and unobfuscated application.

The final difference between the obfuscated and unobfuscated files was that any reference to positions or locals was removed from the obfuscated version. Most of this information was to aid in

debugging so its removal did not affect the application. Figure 17 shows the difference between the unobfuscated and obfuscated outputs of the DisplayMathsActivity class.

Figure 17: Comparison Between dexdump Outputs Showing the Removal of Positions and Locals Information.

In summary, no BuildConfig Class was found, and all references to the source_file_idx were set to an invalid ID. The annotation_off value was set to zero indicating that for every class, all the annotation information was removed. No positions or locals were defined for any of the classes, and every variable was renamed. The full dexdump of the Proguard obfuscation is located in Appendix C.2.

6.2 Java Archive Grinder Fingerprints

The first set of differences between the obfuscated and unobfuscated files was that the `source_file_idx` value was set to an invalid ID, and that all annotation information was removed. In addition, variables were renamed. Java Archive Grinder renamed each of the variables to a lower case letter in the alphabet. At the start of each class it restated the variable names to the beginning of the alphabet. Figure 18 shows a comparison between the obfuscated and unobfuscated applications.

Unobfuscated	Obfuscated

In summary, all references to the `source_file_idx` were set to an invalid ID. The `annotation_off` value was set to zero indicating that, for every class, all the annotation information was removed. No positions or locals were defined for any of the classes and every variable was renamed. The full dexdump of the Java Archive Grinder obfuscation is located in Appendix C.3.

6.3 Zelix KlassMaster Fingerprints

The first difference between the obfuscated and unobfuscated files was that there was no reference to the `BuildConfig` Class. Figure 20 shows that the first class that was found in the obfuscated version, was `'La'`. No reference to `BuildConfig` was found in the obfuscated version, possibly due to class renaming. Either way, `BuildConfig` was not found in the obfuscated version.

Unobfuscated	Obfuscated
Class #0 header:	Class #0 header:

Figure 20: Comparison Between dexdump Outputs for Class #0.

Secondly, the `source_file_idx` value was set to an invalid ID and that all annotation information was removed. In addition, each of the variables were renamed to a lower case letter in the alphabet. At the start of each class it restarted the variable names to the beginning of the alphabet. Figure 21 shows the obfuscated version. Because of how it was obfuscated, it was impossible to find its unobfuscated counterpart. Additionally, any reference to positions or locals was removed from the obfuscated version.

The next difference between the obfuscated and unobfuscated files was that control flow obfuscation was implemented on some of the classes. The example in Figure 22 shows that a group of `goto` instructions were added to the end of the class.

Finally, every string in the obfuscated version was encrypted, and there was a call to a function that would decrypt the string when it was going to be used. Figure 23 shows the instructions for creating a new string, setting that new string to some encrypted set of characters, and then calling the function to decrypt the string.

Figure 23: Obfuscated dexdump Output Showing String Encryption.

6.4 Allatori Fingerprints

Allatori is a commercial product, and the version that was used to obfuscate the Android application was a trial version. Therefore, throughout the dexdump output some, but not all variable names would be set to ALLATORIxDEMO. This would not happen if the Android application was obfuscated with a licensed version of Allatori. Because of this, any identifier that is named ALLATORIxDEMO was not considered as part of the fingerprint.

The first set of differences between the obfuscated and unobfuscated versions was the `source_file_idx` value was set to 140, a value not in the `string_ids` array. All annotation information was also set to a value where no annotation information was located. In addition, the variables and classes were renamed. Allatori renamed each of the variables to a capital letter in the alphabet. Each class name started with 'Lcom/package/' followed by a capital letter. At the start of each class it restated the variable names to the beginning of the alphabet. In addition, all of the variable access types changed to become a synthetic of that type. Figure 24 shows the obfuscated application.

```

Class #1 header:
class_idx      : 17
access_flags   : 17 (0x0011)
superclass_idx : 45
interfaces_off : 0 (0x000000)
source_file_idx : 140
annotations_off : 6548 (0x001994)

Class #1
Class descriptor : 'Lcom/package/G;'

```

Figure 24: Obfuscated dexdump Output Showing `source_file_idx`, `annotation_off`, Variable and Class Name Obfuscation.

Secondly, every string in the obfuscated version was encrypted, and there was a call to a function that would decrypt the string when it was going to be used. Figure 25 shows the instructions for creating a new string, setting that new string to some encrypted set of characters, and then calling the function to decrypt the string.

```
000f8a: 1a01 0a00 |0001: const-string v1, "Bq" // string@000a
000f8e: 7110 2000 0100 |0003: invoke-static {v1}, Lcom/package/e;.d:(Ljava/lang/

000f94: 0c01 |0006: move-result-object v1
000f96: 7110 6b00 0100 |0007: invoke-static {v1}, Ljava/security/MessageDigest;
.getInstance:(Ljava/lang/String;)
Ljava/security/MessageDigest; // method@006b
```

Figure 25: Obfuscated dexdump Output Showing String Encryption.

Finally, any reference to positions or locals was changed to different numbers, that no longer followed the bytecode specification, in the obfuscated version. Changing the numbers does not change how the application runs. In the unobfuscated version, the position line numbers were incremented by one, or some small amount, but always incrementing. Figure 26 shows the difference between the unobfuscated and obfuscated outputs.

Figure 26: Comparison Between dexdump Outputs Showing Positions Obfuscation and the Removal of Locals.

In summary, all references to the `source_file_idx` was obfuscated. The `annotation_off` value was obfuscated. Every variable and class were renamed, the variable access types were changed to become synthetic, and all line numbers were obfuscated. Lastly, every string was encrypted. The full dexdump of the Allatori obfuscation is located in Appendix C.5.

7 Android Obfuscation Fingerprinting Tool

In order to automate the process of finding which obfuscator was used on the Android application, a Python program was developed. This program, titled `aof.py` [35], can be seen in Appendix D. The `aof.py` tool takes a valid APK and checks for a valid `classes.dex` file. Depending on what settings the user applies, the `aof.py` tool will look through the `classes.dex` file looking for the following obfuscations:

Source File IDX Obfuscation

Looks in the class header definitions for the `source_file_idx` field and checks to see if it was set to an invalid ID.

Removal of the BuildConfig Class

Looks in the strings section of the `classes.dex` file for any reference to `BuildConfig`.

Removal of Annotations

Looks in the class header definitions for the `annotations_off` field and checks to see if it was set to zero.

Removal of Debug Information

Looks in each class header definitions for any debug information.

Class Name Obfuscation

Looks in the strings section of the `classes.dex` file for any strings that match any of these patterns, `'Lcom/package/[A-Z]'`, `'L[a-z]'` or `'L[A-Z]'`.

Variable Name Obfuscation

Looks in the strings section of the `classes.dex` file for any strings that match any of these patterns, `'[a-z]'` or `'[A-Z]'`.

Removal of Positions and Locals

Looks in every method for the offset to the location of the positions and locals information, if set to zero then no positions or locals for that method were defined.

String Encryption

Looks in the strings section of the `classes.dex` file and for every string it will count the non-printable characters, and compare it to the total string size. If there are more than 20% of non-printable characters it is assumed that the string has been encrypted.

The `aof.py` tool checks these obfuscations to develop an educated guess on which obfuscator (Proguard, Java Archive Grinder, Zelix KlassMaster, or Allatori) was most likely used. This guess is displayed as a percentage of how many of the obfuscations matched to those that were discovered. While developing the `aof.py` tool, it was tested against the simple Android application that was developed and several Android applications that were downloaded from the Google Play store. Table 1 shows the resulting output of the `aof.py` tool examining the simple Android application that was written. The full results is located in Appendix E.1.

	Proguard	JARG	KlassMaster	Allatori
proguard.apk	99.99%	87.49%	62.49%	24.99%
jarg.apk	87.49%	99.99%	49.99%	12.49%
klassmaster.apk	74.99%	62.49%	99.99%	37.49%
allatori.apk	24.99%	12.49%	37.49%	99.99%

Table 1: Summary of Results From the aof.py Tool When Ran Against the Simple Android Application

From aof.py it shows that for every one of the obfuscated Android applications, that they matched to their corresponding obfuscator 99.99%. In addition the obfuscated applications matched to the other obfuscators due to the overlapping fingerprints. Meaning that some of the obfuscators will match to the same obfuscation in the application, but not all of them. It is important to note that since several obfuscation methods can be done by hand, the aof.py tool will not report a 100% match to any of the obfuscators, it will always be 99.99%. Table 2 shows results from running the aof.py tool against Android applications from the Google Play Store. The full results is located in Appendix E.2.

	Proguard	JARG	KlassMaster	Allatori
Google Chrome	37.49%	24.99%	37.49%	74.99%
Calculator	49.99%	37.49%	49.99%	62.49%
Facebook	37.49%	24.99%	37.49%	74.99%
LED Flashlight	62.49%	49.99%	62.49%	62.49%
Amazon Kindle	24.99%	12.49%	37.49%	87.49%
Google My Business	27.49%	24.99%	37.49%	87.49%
Instagram	37.49%	24.99%	24.99%	74.99%
Netflix	37.49%	24.99%	24.99%	74.99%
Pandora Radio	37.49%	24.99%	37.49%	87.49%
Clash of Clans	62.49%	49.99%	49.99%	49.99%

Table 2: Summary of Results from the aof.py Tool When Ran Against the Android Applications from Google Play Store.

The Google Chrome, Digitalchemy Calculator, Facebook, Amazon Kindle, Google My Business, Instagram, Netflix, and Pandora Radio applications all matched to the Allatori Obfuscator, the LED Flashlight application matched to every obfuscator except Java Archive Grinder, and the Clash of Clans application matched to only Proguard. This result was expected because out of all of the obfuscators, Allatori is the most developed and widely used. It is also important to note that none of the applications matched any of the obfuscators completely. This result was also expected. While it is not known at this point how any of the applications were obfuscated, it is assumed that all of them were. The obfuscation program used in each application can be predicted by the evidence of the obfuscation in the applications.

8 Conclusion

Using a simple Android application and building the application with each of the four obfuscation programs, Proguard, Java Archive Grinder, Zelix KlassMaster, and Allatori, it was possible to find distinct fingerprints for each obfuscator. I found that each of these obfuscators had similar obfuscation rules that ended with similar results. The fingerprints for each obfuscator are summarized here:

Proguard's fingerprint included removing the BuildConfig Class, setting `source_file_idx` values to an invalid ID, removing annotations, positions, and locals, and renaming variables to lower case letters.

Java Archive Grinder's fingerprint included setting `source_file_idx` values to an invalid ID, and removing annotations, positions, and locals from each of the classes.

Zelix KlassMaster's fingerprint included removing the BuildConfig class, positions, and locals, renaming classes and variables to lower case letters, and encrypting all string literals.

Allatori's fingerprint included changing the access type of classes, fields, and methods to a synthetic version, renaming classes, and variables with upper case letters. In addition, Allatori was able to change the `source_file_idx`, `annotations_off`, positions, and locals to values that no longer correlate to the Dalvik bytecode standard.

Proguard, Java Archive Grinder, and Zelix KlassMaster had similar results for a few of the obfuscations. For instance, they all renamed every variable to a lower case letter starting at the beginning of the alphabet. All three programs managed to remove all information from the locals and positions for each class. Even though there are similarities between each of the obfuscators, there was enough of a difference to be able to identify which obfuscator was used.

When running the `aof.py` tool against Android applications from the Google Play Store, it was found that Google Chrome, Digitalchemy Calculator, Facebook, Amazon Kindle, Google My Business, Instagram, Netflix, and Pandora Radio all matched to the Allatori Obfuscator while the LED Flashlight matched to every obfuscator except Java Archive Grinder, and Clash of Clans matched to Proguard. These results show that most of the Android applications used obfuscation that is similar to what Allatori can do.

The obfuscator fingerprints that were discovered could have been manually implemented instead of using one of the obfuscator programs. When a fingerprint was found, there was a chance that it was written by hand and would result in a false positive. This means that the Android Obfuscation Fingerprint Tool, will always return the best educated guess, or whatever obfuscator fingerprint was the most similar.

9 Further Research

The results of this project showed that the four obfuscators examined have overlapping fingerprints. However there are many other obfuscators that need to be examined. Further studies could show that there are other obfuscators that have the same or unique fingerprints. This project would benefit from more testing with a broader range of obfuscators.

Most of the fingerprint identifiers were located in the class headers. While this discovery gives an indication of what obfuscator was used, looking more in depth at the bytecode could provide more detailed information about what obfuscator was used. This could possibly include what string decryption method was called or if any of the obfuscators used different instructions to accomplish the same thing. Either way, looking more in depth at the bytecode would provide more details for identifying obfuscator fingerprints.
